Abstract. Biodiversity enhances ecosystem functions such as biomass production and nutrient cycling. Although the majority of the terrestrial biodiversity is hidden in soils, very little is known about the importance of the diversity of microbial communities for soil functioning. Here, we tested effects of biodiversity on the functioning of methanotrophs, a specialized group of soil bacteria that plays a key role in mediating greenhouse gas emissions from soils. Using pure strains of methanotrophic bacteria, we assembled artificial communities of different diversity levels, with which we inoculated sterile soil microcosms. To assess the functioning of these communities, we measured methane oxidation by gas chromatography throughout the experiment and determined changes in community composition and community size at several time points by quantitative PCR and sequencing. We demonstrate that microbial diversity had a positive overyielding effect on methane oxidation, in particular at the beginning of the experiment. This higher assimilation of CH₄ at high diversity translated into increased growth and significantly larger communities towards the end of the study. The overyielding of mixtures with respect to CH₄ consumption and community size were positively correlated. The temporal CH₄ consumption profiles of strain monocultures differed, raising the possibility that temporal complementarity of component strains drove the observed community-level strain richness effects; however, the community niche metric we derived from the temporal activity profiles did not explain the observed strain richness effect. The strain richness effect also was unrelated to both the phylogenetic and functional trait diversity of mixed communities. Overall, our results suggest that positive biodiversity–ecosystem-function relationships show similar patterns across different scales and may be widespread in nature. Additionally, biodiversity is probably also important in natural methanotrophic communities for the ecosystem function methane oxidation. Therefore, maintaining soil conditions that support a high diversity of methanotrophs may help to reduce the emission of the greenhouse gas methane.

Key words: biodiversity; ecosystem function; mechanisms; methane oxidation; methanotrophic bacteria; niche complementarity; overyielding; soil ecology.

INTRODUCTION

The dramatic loss of biodiversity as a consequence of anthropogenic activities has prompted many experiments that investigated whether and how ecosystem functioning depends on the diversity of the organisms present. To date, most research has focused on aboveground organisms, in particular plants. The majority of these studies have shown a positive relationship between the number of plant species and ecosystem functions such as biomass production. These effects are remarkably consistent across different ecosystem types like grasslands, forests, and marine ecosystems (Balvanera et al. 2006, Cardinale et al. 2012).

Although most studies so far have focused on aboveground organisms, in terrestrial ecosystems, the majority of biodiversity is found belowground. Soil microbial communities are extremely diverse and drive important biogeochemical processes including the decomposition of organic matter

and soil nutrient transformations. Soil microbes also mediate fluxes of greenhouse gases, including methane (CH₄), and therefore are important in light of climate change (Bodelier and Steenbergh 2014). Despite their fundamental significance, little is known to date about the importance of the diversity of these organisms for the functions they promote (Krause et al. 2014b). Positive biodiversity–ecosystem-functioning (BEF) relationships in communities of aboveground macroorganisms have been attributed to three main groups of mechanisms: (1) sampling effects (Aarssen 1997), also known as selection probability effects, refer to the phenomenon that more diverse communities are more likely to contain species that perform particularly well; (2) niche differentiation among species can support the complementary use of resources, thereby reducing competition and allowing for a higher community-level yield (Tilman et al. 1996, Tilman 1997); also, complementarity with respect to enemies will reduce the impact these have if their effect is strongly dependent on the density of hosts (e.g., Maron et al. 2011); (3) facilitation, i.e., positive effects on a species that are mediated by modification of environmental conditions by another species, may also promote a better functioning of mixtures. A frequent case of facilitation in biodiversity experiments is

dinitrogen fixation by legumes (e.g., Spehn et al. 2002). It remains unclear whether and to which extent these groups of mechanisms also operate in soil microbial communities. One reason is that most investigations of BEF relationships in microbial systems to date have been observational studies along environmental gradients (Krause et al. 2014b). In such studies, correlations between diversity and functioning can emerge for many reasons including covariation of diversity with environmental parameters that modify ecosystem functioning independent of diversity. The other reason is that a detailed analyses of mechanisms often requires that a measured community-level function can be broken down into contributions of the component species, which is more challenging in microbial systems than with macroorganisms.

Studies in which microbial diversity has been manipulated directly and systematically have only recently begun to emerge (e.g., Bell et al. 2005, Replansky and Bell 2009, Bier et al. 2015, Fetzer et al. 2015, Delgado-Baquerizo et al. 2016). Many of these studies concerned relatively broad, diversified groups of microbes that drive very general functions such as soil respiration or decomposition. The microbes that carry out these functions often are taxonomically and phylogenetically very diverse and hence there may be high functional redundancy (Nannipieri et al. 2003) and the loss of diversity may, at least initially, have no or only limited consequences. Nevertheless, the few experiments available suggest that niche complementarity can, to some extent, promote community-level functioning through resource partitioning (e.g., Salles et al. 2012).

In the present study, we tested for effects of the diversity of a specialized group of bacteria, the methanotrophs, on their activity and growth. Methanotrophs are obligate aerobic bacteria that oxidize CH₄ and assimilate CH₄-C into biomass. They constitute the most important biotic sink for atmospheric CH₄ and thus play a key role in the CH₄ cycle by affecting atmospheric CH₄ concentrations and the associated greenhouse effect. In wetland systems, methanotrophs together with anaerobic CH₄ oxidizers often oxidize significant fractions of the CH₄ produced by methanogenic Archaea, sometimes over 90%, and therefore substantially reduce CH₄ emissions to the atmosphere (Le Mer and Roger 2001). Based on our current knowledge, methanotrophs are spread over a limited number of phyla, with most members found in the alpha and gamma division of the Proteobacteria (Lücke and Frenzel 2011, Knief 2015). In many ecosystems, their diversity is relatively low with typically up to a few dozen OTUs found (e.g., Levine et al. 2011, Lücke and Frenzel 2011, Siljanen et al. 2011, Serrano-Silva et al. 2014, Knief 2015). The generally limited diversity and high functional specialization of methanotrophs raises the possibility of a low functional redundancy. CH₄ oxidation may therefore be more vulnerable to diversity loss than is typically found for functions driven by more diverse groups of microorganisms with more versatile metabolism. Also, their methanotrophic nature makes them well suited for studying microbial BEF relationships.

Here, we used 10 pure methanotroph strains to create artificial communities composed of 1–10 strains to test for the effects of their biodiversity on their activity and growth. These communities were incubated for six weeks in microcosms with

above-atmospheric headspace CH₄ concentrations. Throughout the experiment, we quantified methanotrophic activity by assessing CH₄ consumption by gas chromatography. Growth of the methanotrophic communities was estimated by measuring the abundance of a gene encoding for the particulate methane monooxygenase (*pmoA*) using quantitative PCR. Finally, we determined the composition of the experimental communities by next-generation sequencing of ribosomal (16S rRNA) and functional gene (*pmoA*) fragments. Our objective was to test whether increased methanotroph diversity promotes CH₄ consumption and the growth of methanotrophic communities. We further tested whether over-yielding of mixed communities was related to functional trait diversity and the phylogenetic relatedness of the strains combined in mixtures, and whether diversity and composition-effects on activity and growth were positively correlated, i.e., whether strain mixtures that over-yielded in terms of community size also showed particularly high CH₄ consumption rates.

MATERIALS AND METHODS

Study species and experimental setup

We created a diversity gradient using 10 strains of methanotrophic bacteria that we grew in pure culture. All aerobic methanotrophic bacteria known to date belong either to the Gammaproteobacteria (type I), Alphaproteobacteria (type II), or Verrucomicrobia (Type III; McDonald et al. 2008, Knief 2015). In our experiment, we used three Type I and seven Type II methanotrophs (Table 1). These strains occur in habitats in which methanogens are active and soil CH₄ concentrations typically high. These methanotrophs exhibit a so called “low affinity” kinetic, i.e., they have a high capacity to oxidize CH₄ but only at concentrations that are well above atmospheric levels (Dunfield et al. 1999). We initially grew all strains in liquid batch cultures in nitrate mineral salt medium (NMS medium; Dedysh et al. 1998). Liquid batch cultures consisted of 100-mL serum flasks with 20 mL NMS medium and 20 mL CH₄ added to the headspace. The liquid batch cultures were kept at 25°C (except *M. capsulatus* at 36°C and *M. tundripaludum* at 23°C) until the cultures reached the stationary growth phase, then at 4°C until they were added to the microcosms.

We constructed microcosms from 50-mL centrifugation tubes (Sarstedt, Nümbrecht, Germany) that we pre-filled with 4 g dry equivalent mass of autoclaved soil from a calcareous meadow (Nenzlingen, Switzerland; 47°33' N, 7°34' E, 520 m above sea level; silty clay loam soil, 41% clay, 52% silt 3.9% C, 0.33% N, pH ≈ 7.8; Niklaus et al. 2003), which has a very low methanotroph abundance (relative abundance of *pmoA* gene measured by qPCR < 0.01% of that measured in inoculated microcosms). We established a methanotroph diversity gradient (1, 2, 4, 6, or 10 strains) in these microcosms by adding 1 mL inoculum and 1.2 mL NMS medium. The inoculum was prepared by mixing aliquots of the pure liquid cultures that had been diluted to approximately 5,000,000 cells/mL with NMS medium based on measurements of their original cell density (CASY Model TTC cell counter, Roche Innovatis AG, Bielefeld, Germany). The amounts of pure culture

inocula that we mixed were inversely proportional to the target strain richness, i.e., all microcosms were inoculated with approximately the same total number of cells. We created 10 different strain compositions at each diversity level except for the 10-strain mixture. The compositions were created by randomly selecting strains, with the restriction that each strain was present in an equal number of mixtures at each diversity level. This ensured that strain richness was varied independently of the average composition found at each diversity level. Each specific composition was replicated in seven separate microcosms, which were placed together in an incubation jar. The most diverse mixture with 10 strains was replicated an additional four times, in four separate jars. One microcosm per jar was immediately frozen at -80°C to assess the strain composition at the beginning of the experiment. The microcosms were then closed with gas-permeable cotton stoppers to minimize the risk of cross-contamination. The jars containing the microcosms were placed in incubators that ran a 24-h temperature cycle (with four periods of 6 h each: 24°C, 26°C, 28°C, 26°C). Every two days, the jars were ventilated to remove the CO₂ produced and new CH₄ was added. The average starting concentration of CH₄ was 9,120 ± 1,140 μL CH₄/L (mean ± SD). One microcosm each was removed from each jar and frozen after 4, 8, 16, 24, 32, and 44 d of incubation for later analysis (see Appendix S1: Fig. S2 for an overview of the experimental setup and sampling).

CH₄ consumption

In order to quantify CH₄ consumption, 30 mL samples were taken from the headspace of each jar at the beginning and at the end of each two-day incubation period, for a total of 32 d. The CH₄ concentration of these samples was determined by gas chromatography (Agilent 7890N gas chromatograph; CH₄ was detected with a flame ionization detector; 12' Porapak Q column; isothermic at 80°C; He carrier gas; CO₂ was determined on the same detector after reducing CO₂ with H₂ on a Ni-catalyst; Agilent Technologies Inc., Santa Clara, California, USA). CH₄ consumption was then determined as apparent first-order oxidation rate constant ($dc/dt = -c \times k$, where *c* is the headspace CH₄ concentration and *k* is the rate constant) by estimating *k* through linear regression of ln(*c*) against time (*t*). We standardized *k* values by dividing these by the number of microcosms in the jar.

DNA extraction

We extracted DNA from the replicate microcosms frozen after 0, 16, and 44 d of incubation. DNA was extracted from the entire soil in the microcosms using the xanthogenate-based extraction method described in Tillett and Neilan (2000) with some adjustments (Appendix S1: Table S1).

Extracted DNA was purified using the PowerClean Pro DNA Clean-Up Kit (MoBio, Carlsbad, California, USA) according to the manufacturer's instruction.

Sequencing of pmoA and 16S gene fragments

To assess changes in community composition, we amplified the variable regions V1 and V2 of the 16S rRNA gene from total nucleic acids extracted after 0, 16, and 44 d of incubations (using primers 9bF and 341R; see Appendix S1: Tables S2 and S3 for details). The fragments of the gene for subunit A of the particulate methane monooxygenase (*pmoA*) were sequenced for the samples taken after 16 d only (primers A189F and M661R; see Appendix S1: Tables S2 and S3 for details). The PCR products obtained were purified with the GeneJET PCR purification kit (Thermo Scientific, Waltham, Massachusetts, USA) and quantified with the 2100 Bioanalyzer high sensitivity DNA kit (Agilent Technologies, Santa Clara, California, USA). Barcoding using the Fluidigm access array technology and paired-end sequencing of the amplified region with the Illumina MiSeq v3 platform was carried out at the Genome Quebec Innovation Center, Montreal, Canada.

Analysis of the 16S rRNA and the *pmoA* gene sequences was performed according to a customized pipeline published in Frey et al. (2016). However, as we knew the strains present, we did not perform OTU clustering and taxonomic assignment but instead mapped the reads directly against the known 16S rRNA and *pmoA* sequences of our strains. We used algorithms from USEARCH v8 (Edgar 2010) unless otherwise stated. Forward and reverse read pairs were merged using the fastq_mergepairs algorithm (Edgar and Flyvbjerg 2015, minimum overlap between forward and reverse read pairs 50 base pairs [bp], minimum merged read length of 300 bp). PCR primers were detected and removed with Cutadapt (Martin 2011). Trimmed sequences were then quality-filtered using the fastq_filter function (Edgar and Flyvbjerg 2015) with a maximum expected error threshold of one. All quality-filtered reads were mapped against the known 16S rRNA and *pmoA* sequences of the methanotroph strains we had used to create the experimental biodiversity gradient (sequences were retrieved from GenBank but verified by Sanger-sequencing the pure methanotroph cultures) using the usearch_global algorithm (Edgar 2010; options id = 99, maxrejects = 0, maxaccepts = 0, and top hit only). We then counted the number of matched sequences of each strain in each sample.

Presence/absence of strains based on *pmoA* data (day 16) matched the ones for 16S. Since *Methylocella silvestris* was not detectable in the *pmoA* sequence data due to a lack of *pmoA* gene we used 16S rRNA-based abundance data to calculate diversity indices. We calculated the relative abundance of each strain in all the samples based on the number of matching 16S rRNA gene copies. From this, the realized strain richness was calculated (i.e., number of strains that remained after a certain time) by counting the strains with a relative abundance of more than 0.1%; this minimum abundance was chosen to exclude effects of spurious contaminations. We further calculated the Shannon diversity index (H') and from that effective strain richness ($e^{H'}$), which gives the low-abundant strains a lower weight. Right after inoculation

(day 0), not enough DNA could be extracted to obtain a reliable diversity estimate by sequencing. Diversity indices for day 16 were similar to the ones for day 44, and we therefore based our calculations of realized and effective strain richness on 16S rRNA gene sequencing information from day 44.

Numbers of pmoA copies

We determined the abundances of methanotrophic *pmoA* gene copies by quantitative PCR (StepOne real-time PCR system Applied Biosystems, Foster City, California, USA; see Appendix S1: Tables S2 and S3 for details). The number of *pmoA* gene copies in the genome were not known for all strains in our experiment; however, where known, methanotrophs had one or two gene copies except for *Methylocella silvestris*, which has a soluble instead of a particulate methane mono-oxygenase and therefore lack the *pmoA* gene. Nevertheless, we used number of *pmoA* copies as proxy of methanotroph community size; 16S sequence analysis indicated that *Methylocella silvestris* was among the least abundant methanotrophs, and the lack of *pmoA* gene in this strain likely did not substantially bias our community size estimate. A serial dilution of purified DNA from *Methylococcus capsulatus* (quantified with the Qubit fluorometer; Invitrogen, Carlsbad, California, USA) was included in duplicates in each run to determine the calibration curve. The efficiency values of the runs calculated from the slopes of the calibration curves were between 72% and 83%.

Functional and phylogenetic diversity

To estimate phylogenetic diversity, we calculated a phylogenetic tree (UPGMA) with the EMBL-EBI MUSCLE online tool (Edgar 2004, McWilliam et al. 2013) using *pmoA* sequences of our strains plus a collection of 67 additional sequences (retrieved from GenBank using accessions from Lüke and Frenzel 2011). To include *Methylocella silvestris* in the tree, which doesn't have a *pmoA* gene, we used the *pmoA* sequence of *Methylocapsa aurea* instead (accession no FN433470). Of the available methanotrophs that have a *pmoA* gene, *M. aurea* shows the highest 16S rRNA sequence similarity to *M. silvestris*. The phylogenetic diversity (PD) of each community was calculated as the total branch length of the subtree defined by the strains in the mixture (calcPD function from library pddiv, available online).⁸ Functional diversity (FD) was calculated similarly, using a trait dendrogram (Petchey and Gaston 2006) constructed from traits available from the literature (Table 1; calcFD function in R library pddiv). We used Gower distances in the distance matrix underlying the trait dendrogram because this metric is preferable when combining continuous and binary traits.

Statistical analysis

We used analysis of variance based on general linear models (R 3.0; R Core Team 2013) to test for relationships between each of our measures of diversity (applied, realized and effective strain richness, PD, FD) and the methanotroph activity and community size. As is standard in the analysis

⁸ <https://github.com/pascal-niklaus/pddiv>

of biodiversity experiments (Schmid et al. 2017), we used the specific composition of the community as replicate; this was achieved by averaging the four technical replicates of the 10-strain community before analysis. All measures of diversity were included in the model in log-transformed form; the reason for this is that typically BEF relationships are “positive decelerating” (Cardinale et al. 2011), and that this relationship is linearized by log-transforming diversity.

The main dependent variables were the cumulative CH₄ consumption over the duration of the incubation (indicated by the mean first order CH₄ consumption rate constant), and the net methanotrophic growth (indicated by *pmoA* copy numbers at day 44). To achieve a homoscedastic distribution of the residuals, we square root-transformed the first-order rate constant for CH₄ consumption. To test whether the presence of particular strains in the communities had an important effect on our dependent variables beyond the overall effect of strain diversity, we also added presence/absence contrasts for the 10 strains (effects of the different strains tested in separate models).

Inspection of data revealed three distinct phases in the course of the incubation. In addition to analyzing cumulated CH₄ consumption, we therefore also analyzed mean CH₄ consumption for the initial phase of the study where fast growth was observed (days 0 to 10), the middle period with highest CH₄ consumption (days 12 to 20), and the final phase of the incubation that was characterized by lower CH₄ uptake rates (days 22 to 32).

We further inspected whether effects of strain richness on CH₄ consumption were related to methanotrophic community size. To do so, we assigned the *pmoA* copy numbers of day 0, 16, and 44 to the initial, middle, and final phase, respectively. Then, for each time period, we fitted linear models in which applied strain richness was followed by *pmoA* copy number, and vice versa. The first model yielded tests for overall effects of strain richness, whereas the second model yielded tests for effects of strain richness beyond any effect that was already explained by variation in community size.

The different strains exhibited different temporal dynamics in monoculture, with some performing particularly well at the beginning of the experiment and some at the end. We therefore tested for effects of temporal complementarity on CH₄ consumption and community size by estimating the size of the “community niche” CN (Salles et al. 2009): for each measurement day, we determined the maximum CH₄ consumption rate of the monocultures of the strains present in the mixture, and summed these values. CN thus quantifies the cumulative CH₄ consumption that would be achieved if community-level consumption was determined by the strain performing best on that particular day. We used CN as explanatory variable in further linear models, fitting this term before and after strain richness.

We quantified the over-performance (net biodiversity effect) of all mixtures for both CH₄ consumption and *pmoA* copy numbers. For CH₄ consumption, over-performance was calculated from mean consumption rates over the entire experiment. For *pmoA* copy numbers, we calculated over-performance (overyielding) for day 44. The expected value for each mixture was calculated by averaging the values measured for the monocultures microcosms in the experiment of the strains present in the mixture. The over-performance

was calculated as observed minus expected CH₄ consumption and *pmoA* copy numbers. We used a one-sample, one-sided Student's *t* test to test for over-performance of mixtures in relation to monocultures. We then used linear models to test whether the over-performance of mixtures depended on the number of strains they contained. Finally, we tested whether over-yielding of *pmoA* copies correlated with the over-performance of the same mixtures with respect to CH₄ consumption.

RESULTS

Community compositions

We obtained $(41 \pm 11) \times 10^3$ bacterial 16S rRNA sequences per microcosm (in total 5.4×10^6 16S rRNA sequences [mean $\pm$ SE]) and $(41 \pm 8.4) \times 10^3$ *pmoA* sequences per microcosm (in total 1.8×10^6 *pmoA* sequences). After quality control, 1.3×10^6 16S rRNA sequences could be mapped to 1 of the 10 strains used for creating the communities and 2.8×10^5 *pmoA* sequences could be mapped to the nine strains that possess a *pmoA* gene. Overall, the number of 16S rRNA sequences that belonged to 1 of out 10 strains increased over the course of the experiment, while the number of other non-methanotroph 16S rRNA sequences decreased. The 16S rRNA sequences that did not match any of the 10 strains we added was likely DNA from various soil bacteria that had remained in the soil matrix. This DNA slowly degraded over the course of the experiment.

The starting composition of the methanotroph communities based on the 16S rRNA sequences was consistent with the strains that were added. While the number of sequences varied between samples, within sample the number of sequences for each strain was quite even. The composition of methanotroph communities in the different mixtures changed over time. In general, the strain distribution became more uneven through time, with experimental communities dominated by one or a few strains at the end of the experiment. The different strains performed differently well in our microcosms: *Methylocystis echinoides* became dominant in many but not all mixtures; in some communities other strains became dominant even when *Methylocystis echinoides* was present. No single strain was entirely lost from the experiment but *Methylococcus capsulatus* and *Methylobacter tundripaludum* disappeared from 87% and 50% of the communities in which they were originally present, respectively. *Methylocystis echinoides* and *Methylosinus trichosporium* persisted in all communities. The extinction of the other strains ranged from 12% to 37% of the communities.

Despite these strain-specific effects, the experimental methanotroph diversity gradient persisted throughout the study. Both realized strain richness and Shannon-based effective strain richness (calculated based on 16S rRNA sequences after 44 d) were highly significantly correlated with applied strain richness (Pearson's product moment correlation $r = 0.82$ and 0.46 , $P < 0.001$ for both indices; Appendix S1: Fig. S1). The realized strain richness was higher than expected in some monocultures and two-strain mixtures, likely because of cross-contamination during handling in the laboratory.

Community size

Average *pmoA* gene copy numbers increased throughout the experiment, with the largest increase between days 0 and 16. After 44 d, *pmoA* copy numbers were significantly positively correlated with applied strain richness (applied strain richness, $P = 0.03$; Fig. 1) and marginally significantly with realized strain richness (realized strain richness, $P = 0.06$). These effects already began to develop earlier (day 16) but were not statistically significant. Effective strain richness, phylogenetic diversity (PD), and functional diversity (FD) were not statistically significantly related to *pmoA* copy numbers at any date.

When including the presence/absence of the strains in the model, communities with *Methylocystis parvus* had significantly higher copy numbers ($P < 0.01$) and *Methylosinus trichosporium* ($P < 0.05$) significant lower copy numbers (test after adjusting for strain richness).

CH₄ consumption

Over the course of the experiment, CH₄ consumption increased until day 10, remained stable until day 16 and then decreased (Fig. 2). Differences in CH₄ consumption between the samples and over time ranged from almost no consumption to consuming nearly all the added CH₄ within the two-day period. Over the entire measurement period of 32 d, average CH₄ consumption increased statistically significantly with applied strain richness ($P = 0.03$; Fig. 3). Neither realized nor effective strain richness, FD or PD explained any significant fraction of the variation observed in CH₄ consumption. Models including presence-absence contrasts after the effect of applied strain richness indicated that communities with either *Methylobacter tundripaludum* ($P < 0.01$) or *Methylocella silvestris* ($P < 0.05$) consumed particularly little CH₄.

When analyzing the period of most rapid growth separately (days 0–10), CH₄ consumption increased significantly with applied strain richness ($P < 0.05$), but not with realized

strain richness, effective strain richness, PD, or FD. For the intermediate period characterized by high CH₄ consumption (days 12–20), there was no significant relationship between CH₄ consumption and any of the diversity measures though effects of applied strain richness were marginally significant ($P = 0.06$). We did not find any diversity effects for the last phase of the experiment (days 22–32).

When including numbers of *pmoA* gene copies as an explanatory covariate before applied strain richness, in the first and intermediate period, effects of applied strain richness were statistically significant ($P < 0.05$) but *pmoA* copy numbers were not. In the final period, effects of strain richness were no longer significant but effects of *pmoA* copy number were ($P < 0.05$).

The community niche metric (CN) we calculated from temporal monoculture CH₄ consumption profiles (Appendix S1: Fig. S3) was highly correlated with applied strain richness (Pearson's product moment correlation $r = 0.86$; $P < 0.001$) but CN did not explain significant amounts of variation in cumulated CH₄ consumption, regardless of whether CN was fitted before or after applied species richness.

Over-performance of strain mixtures and effects of individual strains

We observed an over-performance of strain mixtures both with respect to CH₄ consumption (first-order uptake rate constant) and community size (number of *pmoA* gene copies). Almost all strain mixtures consumed more CH₄ than would have been expected based on the mean CH₄ consumption of their monocultures ($P < 0.001$; Fig. 4). The net biodiversity effect (observed minus expected CH₄ consumption) was positive but not significantly related to any of the diversity indices.

Mixtures also showed over-yielding with respect to number of *pmoA* gene copies. As expected based on the constant amount of inoculum added, there was no statistically significant difference between observed and expected number of copies at the start of the incubation. After 44 d of growth, the numbers of *pmoA* gene copies of mixtures exceeded average numbers of copies of monocultures of the component strains ($P < 0.001$). Similar to CH₄ consumption rates, the net biodiversity effect on number of *pmoA* gene copies was positive but not significantly related to any of the diversity indices.

Net biodiversity effects for CH₄ consumption and for community size were positively correlated (Pearson's product moment correlation $r = 0.45$; $P < 0.004$; $R^2 = 0.18$). Strain mixtures that exhibited higher than expected CH₄ consumption based on their component monocultures also produced larger communities than expected.

DISCUSSION

Here we explored the biodiversity–ecosystem-function (BEF) relationship in a specialized group of bacteria, the methanotrophs. We demonstrated that increased methanotrophic strain diversity significantly promotes CH₄ consumption rates, growth, and resulting community size. In other words, mixtures of strains consumed CH₄, on average, at higher rates and grew more than monocultures of the strains they contain.

FIG. 1. Mean number of *pmoA* gene copies per microcosm by applied strain richness at the beginning (open circle, dashed line, not significant [n.s.]) and at the end of the experiment (solid circle, solid line, $P < 0.03$). Error bars show the standard error for the different compositions ($n = 10$ except for the 10-strain mixture, which consists of only one specific composition that was replicated four times).

FIG. 2. Temporal change in apparent first-order CH_4 uptake rate constants k for each diversity level. Lines show mean values with gray areas indicating standard errors using different communities as replicates ($n = 10$) except for the 10-strain mixture where technical replicates ($n = 4$) of the same composition are used.

While positive BEF relationships have been found as a general trend in studies of plant communities, this study is one of a few experimental studies available to date that demonstrate a positive BEF relationship in communities of microorganisms (e.g., Wohl et al. 2004, Bell et al. 2005, Replansky and Bell 2009, Salles et al. 2009, 2012, Philippot et al. 2013, Delgado-Baquerizo et al. 2016). In other studies no significant BEF relationship was found (e.g., Griffiths et al. 2000, 2001, Seghers et al. 2003, Wertz et al. 2006, 2007), and some microbial model systems even revealed negative BEF relationships, which were ascribed to more frequent antagonistic interactions in more diverse system, for example through the production of toxins (Jousset et al. 2011, Becker et al. 2012). Interestingly, in our study, methanotrophic strain richness was the best predictor of effects on CH_4 consumption and methanotrophic growth. Effective strain richness did not explain much variation in our data, indicating that strains low in abundance are important for

the maintenance of ecosystem functioning (Bodrossy et al. 2003, Bodelier et al. 2013). Ultimately, BEF relationships arise from functional differences among strains; functional diversity (FD) therefore often explains more variation in community functioning than strain richness alone (Krause et al. 2014b), but we found no relationship between FD and CH_4 oxidation rates or growth of methanotrophs in our study. In particular, FD did not explain significant fractions of variation in our data that were not already explained by strain richness. One reason for the lack of explanatory power of our FD metric may have been that we did not include the trait measures or combinations of these that were relevant in our experimental context. Or alternatively, that we included

FIG. 3. The mean first-order CH_4 uptake rate constant k (averages over the 32 d of measurement) increased significantly with the logarithm of applied strain richness ($P < 0.03$). Line and error bars show model-predicted means and standard errors. Note square-root transformed scale of the y-axis.

FIG. 4. Over-performance of strain mixtures relative to monocultures with respect to CH_4 consumption (measured as apparent first-order CH_4 consumption constant). For most mixtures, the observed CH_4 oxidation constant k is higher than the expected CH_4 oxidation constant k . The expected constant k was calculated by taking the mean of the values measured for the monocultures of the strains that were in the mixture. The dashed line indicates the 1:1 relationship.

traits that have no functional implications and therefore added “noise” to our predictor. Growth-relevant traits are more difficult to determine for microorganisms than for higher plants, and only a few traits were consistently available for all strains. In plants, traits such as specific leaf area or root–shoot ratios are known to define growth strategies. In analogy, we focused on maximum growth rate and measures that may have allometric implications such as the size of cells or whether these form aggregates. We reasoned that these could affect surface to volume ratios and therefore specific activities. Other obvious candidate traits are the kinetic characteristics of CH₄ consumption, but these are notoriously difficult to estimate because CH₄ uptake rates in laboratory systems are affected by diffusion limitations in the medium in which the organism grows (Dunfield and Conrad 2000). Also, these traits may be very plastic, allowing acclimation to environments with different resource supply. Finally, all methanotrophs critically rely on CH₄ supply, which may lead to phenotypic convergence, in particular in the absence of spatiotemporal heterogeneity in CH₄ concentrations. Niche complementarity that promotes biodiversity effects may thus be in other functional dimensions, which could for example be related to biotic interactions or to the uptake of other nutrients.

Some of the difficulties in determining the relevant functional traits can be circumvented by using phylogenetic distance as proxy of niche complementarity. Several studies have shown that this can work well in communities of higher plants, suggesting that the relevant traits are conserved as species evolve (Flynn et al. 2011). However, this may not be true for all organisms and traits (Crisp and Cook 2012). Evolutionary change can happen rapidly in microbes, potentially leading to a weaker phylogenetic signal for less conserved traits (Martiny et al. 2013). In our study, the phylogenetic diversity (PD) of methanotrophs did not predict their community-level functioning. Methanotrophs in particular have shown a weak phylogenetic signal in physiological traits relevant to CH₄ oxidation (Krause et al. 2014a), suggesting that the traits are not highly conserved. Additionally, some of the strains used in this experiment are rather closely related, which might underestimate the functional diversity that is there and which promotes community-level functioning. For example, differences in metabolic responses have been found even between closely related strains of methanotrophs (Hoefman et al. 2014). So PD may not be a good proxy for FD in the case of methanotrophs and not suitable for explaining BEF relationships.

In our experiment, effects of diversity first manifested in higher CH₄ consumption and towards the end of the experiment in a larger community size. This sequence of events can be understood in the light of CH₄ assimilation being the process that drives the growth of the communities. Eller and Frenzel (2001) reported a similar pattern in microcosms with rice paddy model systems in which activity and methanotroph cell counts were negatively correlated through time and cell counts increased even after activity had started to decrease.

Both CH₄ consumption and methanotrophic community growth show over-yielding in mixtures compared to monocultures, i.e., on average, mixtures consumed more CH₄ and grew more than would have been expected based on the performance of monocultures of the strains they contained.

Over-yielding of community size and CH₄ consumption were positively correlated, indicating that mixtures that consumed CH₄ at particularly high rates also grew more. Biodiversity effects with macro-organisms are often classified as complementarity or selection effects by using statistical partitioning schemes (Loreau and Hector 2001). In our study, almost all mixtures showed over-yielding, suggesting that biodiversity effects were not just driven by a few very productive strains (which would be typical for sampling-type effects). Our data did not reveal evidence for large effects of the presence of particular strains. This observation is in agreement with the assumption that complementarity effects drove the observed diversity effects. However, we were not able to test these in a more strict sense because we could not trace back community-level measurements to contributions of particular strains, which is required for, e.g., the additive partitioning method (Loreau and Hector 2001). Monoculture data revealed different growth rates and different periods of maximum activity for the different strains, suggesting that temporal complementarity could have been important. However, temporal complementarity, quantified as community niche, did not explain much variation in our data. Nevertheless, such a temporal niche partitioning may help to stabilize methanotrophic activity in natural and semi-natural wetlands. Environmental changes due to seasonality, management (e.g., water level changes, fertilizer application, crop harvesting), or irregular climatic events (e.g., drought) will disturb methanotrophic communities. These will respond with a temporal succession of species (Collet et al. 2015, Ho et al. 2016a, b), a process that will only stabilize function through time if a sufficiently diverse pool of taxa is available.

In this study, we show a significant biodiversity–ecosystem-function relationship in methanotrophic bacteria. To date, only a few other studies are available in which the diversity of microorganisms was manipulated directly via assembly of pure strains (Wohl et al. 2004, Bell et al. 2005, Salles et al. 2009, 2012, Gravel et al. 2011), allowing to infer causal effects of biodiversity on functioning (Krause et al. 2014b). Our study demonstrates that BEF relationships can show similar patterns in microbial communities to those found in communities of higher organisms, for example plants. Our findings support the importance of biological diversity for driving particular ecosystem functions. Moreover, they also demonstrate that BEF relationships show similar patterns at different scales and in different types of organisms and are therefore likely widespread in nature. Methanotrophs are important for the regulation of CH₄ emissions (Le Mer and Roger 2001), as they act as a “filter” and oxidize the CH₄ produced in anaerobic environments before it enters the atmosphere. We show in our experiment that a loss in diversity significantly decreases the CH₄ oxidation and observational studies suggest that diversity may also be important in natural methanotrophic communities for maintaining CH₄ oxidation and to increase its temporal stability (Mohanty et al. 2006, Levine et al. 2011, Siljanen et al. 2011, Bodelier et al. 2013).

ACKNOWLEDGMENTS

This project was funded by the Swiss National Science Foundation (grant 144065 to P. A. Niklaus) and the University of Zurich. We gratefully acknowledge Sascha Krause and Marion Meima for the provision of some of the methanotroph cultures we used. We thank

René Husi and Andy Lutz for help with laboratory analysis. We further are indebted to Kentaro Shimizu and the Genetic Diversity Centre (GDC), ETH Zurich for generous help with laboratory facilities. P. A. Niklaus acknowledges support from the University of Zurich Research Priority Programme Global Change and Biodiversity.
